

PyTTE: The Technical Document

Version 0.3

Ari-Pekka Honkanen

April 15, 2020

1 Introduction

PyTTE (pronounced *pie-tee-tee-ee*) is a Python package for solving X-ray diffraction curves of bent crystals in reflection and transmission geometries. The computation of the diffraction curves is based on the numerical integration of 1D Takagi-Taupin equation (TTE) which is derived from a more general Takagi-Taupin theory describing the propagation of electromagnetic waves in a (quasi)periodic medium. Both energy and angle scans are supported. This document describes the theoretical basis behind PyTTE.

2 Takagi-Taupin equation

In the typical two-beam case where the incident wave is written as $\mathbf{D}_0(\mathbf{r}) \exp(i\mathbf{k}_0 \cdot \mathbf{r})$ and the diffracted wave as $\mathbf{D}_h(\mathbf{r}) \exp(i\mathbf{k}_h \cdot \mathbf{r} - i\mathbf{h} \cdot \mathbf{u})$, the Takagi-Taupin equations can be written as

$$\begin{cases} \frac{\partial D_0}{\partial s_0} = ic_0 D_0 + ic_{\bar{h}} D_h \\ \frac{\partial D_h}{\partial s_h} = i \left(c_0 + \beta + \frac{\partial(\mathbf{h} \cdot \mathbf{u})}{\partial s_h} \right) D_h + ic_h D_0, \end{cases} \quad (1a)$$

$$(1b)$$

where D_0 and D_h are the pseudoamplitudes of the incident and diffracted waves, and s_0 and s_h coordinates along their direction of propagation, respectively. The deformation of the crystal is contained in $\mathbf{h} \cdot \mathbf{u}$ which will be considered in detail later. The coefficients $c_{0,h,\bar{h}}$ are given by

$$c_0 = \frac{k\chi_0}{2} \quad c_{h,\bar{h}} = \frac{kC\chi_{h,\bar{h}}}{2}, \quad (2)$$

where $k = 2\pi/\lambda$ and $C = 1$ for σ -polarization and $\cos 2\theta_B$ for π -polarization. The deviation parameter $\beta = (k_h^2 - k_0^2)/2k_h$ is quite often approximated by $\beta \approx k\Delta\theta \sin 2\theta_B$, where $\Delta\theta$ is the deviation from the Bragg angle. However, since this approximation ceases to be valid near the backscattering condition, PyTTE uses a more general form

$$\beta = \frac{2\pi}{d_h} \left(\sin \theta - \frac{\lambda}{2d_h} \right) = h \left(\sin \theta - \frac{\lambda}{2d_h} \right), \quad (3)$$

where d_h is the interplanar separation of the diffractive planes corresponding to the reciprocal vector \mathbf{h} and θ is the incidence angle relative to the aforementioned planes. To avoid the possibility of catastrophic cancellation, the subtraction is performed explicitly with 64 bit floating point numbers.

The partial derivatives with respect to s_0 and s_h can be written in Cartesian coordinates as

$$\frac{\partial}{\partial s_0} = \cos \alpha_0 \frac{\partial}{\partial x} - \sin \alpha_0 \frac{\partial}{\partial z} \quad \frac{\partial}{\partial s_h} = \cos \alpha_h \frac{\partial}{\partial x} + \sin \alpha_h \frac{\partial}{\partial z}. \quad (4)$$

The incidence and exit angles α_0 and α_h with respect to the crystal surface are related to θ by $\alpha_0 = \theta + \varphi$ and $\alpha_h = \theta - \varphi$, where φ is the asymmetry angle (positive clockwise). When seeking a solely depth-dependent solution for D_0 and D_h , we may drop the x -derivatives and thus obtain

$$\begin{cases} \frac{dD_0}{dz} = -i\gamma_0 c_0 D_0 - i\gamma_0 c_h D_h \\ \frac{dD_h}{dz} = i\gamma_h \left(c_0 + \beta + \frac{\partial(\mathbf{h} \cdot \mathbf{u})}{\partial s_h} \right) D_h + i\gamma_h c_h D_0, \end{cases} \quad (5a)$$

$$(5b)$$

where $\gamma_0 = 1/\sin \alpha_0$ and $\gamma_h = 1/\sin \alpha_h$. By defining $\xi = D_h/D_0$, the equations can be written as a single ordinary differential equation

$$\frac{d\xi}{dz} = i\gamma_0 c_h \xi^2 + i \left[(\gamma_0 + \gamma_h) c_0 + \gamma_h \beta + \gamma_h \frac{\partial(\mathbf{h} \cdot \mathbf{u})}{\partial s_h} \right] \xi + i\gamma_h c_h \quad (6)$$

In the reflection geometry (*i.e.* the Bragg case), the reflectivity R of the crystal with thickness t can be solved by integrating Equation (6) from the bottom of the crystal $z = -t$ to the top surface $z = 0$. The initial condition is set $\xi(-t) = 0$. The reflectivity, which is defined in the terms of integrated intensity, is then computed $R = \gamma_0/\gamma_h |\xi(0)|^2$ where γ_0/γ_h takes care of different footprint sizes in the asymmetric case. Using the solved ξ and Equation (5a), the transmission $T = |D_0(-t)/D_0(0)|^2$ can be then solved from

$$\frac{dD_0}{dz} = -i(\gamma_0 c_0 + \gamma_0 c_h \xi) D_0 \quad (7)$$

by integrating from $z = 0$ to $z = -t$. The transmission geometry (the Laue case) is more straightforward, as the ODEs for ξ and D_0 can be integrated simultaneously from $z = 0$ to $z = -t$. With the initial conditions are set $\xi(0) = 0$ and $D_0(0) = 1$, the forward-diffracted intensity at the exit surface is $|D_0(-t)|^2$ and the diffracted intensity is $|D_h(-t)|^2 = |\xi(-t)D_0(-t)|^2$.

2.1 Susceptibilities and structure factors

In linear media, the susceptibility χ is related to the dielectric constant ϵ by $\epsilon = \epsilon_0(1 + \chi)$ where ϵ_0 is the vacuum permittivity [1]. Since χ is small, the complex refractive index is thus $n = \sqrt{\epsilon} \approx 1 + \chi/2$. The connection between the refractive index and the atomic form factor is [2]

$$n = 1 - \frac{r_0 \lambda^2}{2\pi} \sum_j n_j f_j \quad (8)$$

where r_0 is the classical electron radius, n_j and f_j are the number density and the form factor of atomic species j , respectively. For crystalline matter, the phase factor and the Debye-Waller factors are included in the sum

$$\chi(\mathbf{q}) = -\frac{r_0 \lambda^2}{\pi V} \sum_i e^{i\mathbf{q} \cdot \mathbf{R}_i} \sum_j f_j(\mathbf{q}) e^{i\mathbf{q} \cdot \mathbf{r}_j} e^{-\frac{1}{2} q^2 \langle u_j^2 \rangle} \quad (9)$$

where V is the volume of the crystal. The first sum goes over all the lattice points i , and the second one the atoms in the unit cell. The Fourier coefficients of the series $\chi(\mathbf{r}) = \sum_{\mathbf{h}} \chi_{\mathbf{h}} e^{i\mathbf{h} \cdot \mathbf{r}}$ are thus

$$\chi_{\mathbf{h}} = -\frac{r_0 \lambda^2}{\pi v} F_{\mathbf{h}} \quad (10)$$

where v is the volume of the unit cell, and the crystal structure factor is

$$F_{\mathbf{h}} = \sum_j f_j(\mathbf{h}) e^{i\mathbf{h} \cdot \mathbf{r}_j} e^{-\frac{1}{2}h^2 \langle u_j^2 \rangle}. \quad (11)$$

PYTTTE uses `Crystal_F_H_StructureFactor` of XRAYLIB to calculate the structure factors F_h . In this case the user given Debye-Waller factor is assumed to be $\exp(-\frac{1}{2}h^2 \langle u^2 \rangle)$ which is passed to calculation of F_h and $F_{\bar{h}}$; the Debye-Waller factor is always 1 for F_0 . Although not explicitly stated, XRAYLIB apparently assumes the form of the Fourier expansion to be $\sum_{\mathbf{h}} \chi_{\mathbf{h}} e^{-i\mathbf{h} \cdot \mathbf{r}}$ due to which the structure factors are complex conjugated in PYTTTE before calculating $\chi_{\mathbf{h}}$. According to the XRAYLIB source code and the example files (e.g. `example/xrlexample1.c`) the input parameter `rel_angle` is set to 1.

2.2 Scan vector and refraction correction

The scan vector, whether in the energy or angle domain, is given to PYTTTE relative to the kinematical diffraction condition $\lambda = 2d_h \sin \theta$, or equivalently $\beta = 0$. However, it is well-known [3] that due to the refraction of X-rays at the crystal-vacuum interface, the diffraction is not exactly at where the kinematical condition suggests it to be. From Eq. (6) we see, that the true center of the diffraction takes place at $\beta = -(1 + \gamma_0/\gamma_h)\text{Re}[c_0]$. Compared to the kinematical condition, the energy of the centre of the diffraction is changed by

$$\frac{\Delta E}{E} = - \left(1 + \frac{\gamma_0}{\gamma_h}\right) \frac{\text{Re}[\chi_0]}{4 \sin^2 \theta} \quad (12)$$

and the angle by

$$\Delta \theta = - \left(1 + \frac{\gamma_0}{\gamma_h}\right) \frac{\text{Re}[\chi_0]}{4 \sin \theta \cos \theta}. \quad (13)$$

The refraction corrections can be applied to the scan vector if needed.

2.3 Automatic scan limit calculation

Locally, the diffraction takes place most efficiently in the crystal when

$$\left(1 + \frac{\gamma_0}{\gamma_h}\right) \text{Re}[c_0] + \beta + \frac{\partial(\mathbf{h} \cdot \mathbf{u})}{\partial s_h} = 0 \quad (14)$$

in Eq. (6), which is effectively Bragg's law corrected for the refraction and influence of deformation. The scan limits can be thus be calculated by finding the maximum and minimum values for the deformation term inside the crystal and calculating the corresponding β -range. In addition we have to take into account that every reflection has a finite width and extend the scan range accordingly. According to [4], the Darwin width of a perfect thick crystal in the case of symmetric Bragg reflection is

$$\Delta \theta_D = \frac{2\sqrt{|\chi_h \chi_{\bar{h}}|}}{\sin 2\theta_B} \quad (15)$$

except near $\theta_B = \pi/2$ when

$$\Delta \theta_D = \left(2\sqrt{|\chi_h \chi_{\bar{h}}|}\right)^{1/2}. \quad (16)$$

is more appropriate. For scan limit calculation purposes we combine the two expressions continuously in the following way:

$$\Delta\theta_D(\theta_B) = \begin{cases} \left(2\sqrt{|\chi_h\chi_{\bar{h}}|}\right)^{1/2} & \text{when } \sin 2\theta_B \leq \left(2\sqrt{|\chi_h\chi_{\bar{h}}|}\right)^{1/2} \\ \frac{2\sqrt{|\chi_h\chi_{\bar{h}}|}}{\sin 2\theta_B} & \text{when } \sin 2\theta_B > \left(2\sqrt{|\chi_h\chi_{\bar{h}}|}\right)^{1/2} \end{cases} \quad (17)$$

Substituting this in Eq. (3) and expanding up to the first order, we get

$$|\Delta\beta| = \sigma h \Delta\theta_D(\theta_B) \cos \theta_B, \quad (18)$$

where $\sigma = 2$ is a scaling factor which makes the scan range look nicer especially in the absence of a deformation field. Therefore the scan limits are

$$\beta_{\min} = -\frac{k}{2} \left(1 + \frac{\gamma_0}{\gamma_h}\right) \text{Re}[\chi_0] - \max \left[\frac{\partial(\mathbf{h} \cdot \mathbf{u})}{\partial s_h} \right] - \sigma h \Delta\theta_D(\theta_B) \cos \theta_B \quad (19)$$

$$\beta_{\max} = -\frac{k}{2} \left(1 + \frac{\gamma_0}{\gamma_h}\right) \text{Re}[\chi_0] - \min \left[\frac{\partial(\mathbf{h} \cdot \mathbf{u})}{\partial s_h} \right] + \sigma h \Delta\theta_D(\theta_B) \cos \theta_B \quad (20)$$

It should be noted, that the limits above do not aim to be perfect but act more like as a suggestion. For example, the Darwin width term used may fall short if the crystal is strongly bent or very thin. Also, the first order expansion of β is not accurate in the back-scattering.

3 Deformation

As stated in the previous section, the deformation is introduced through $\partial_h(\mathbf{h} \cdot \mathbf{u})$ term where \mathbf{u} is the displacement vector field. Taking the asymmetry into account, the reciprocal vector is given by $\mathbf{h} = h \sin \varphi \hat{\mathbf{x}} + h \cos \varphi \hat{\mathbf{z}}$. Thus

$$\frac{\partial(\mathbf{h} \cdot \mathbf{u})}{\partial s_h} = h \sin \varphi \frac{\partial u_x}{\partial s_h} + h \cos \varphi \frac{\partial u_z}{\partial s_h}. \quad (21)$$

Again we write the partial derivatives in terms of x and z . In this case, however, neither x - or z -derivatives can be dropped as they both contain physical information about the rotation and the separation of the diffractive planes. Since the beam propagates also in the x -direction, the situation is not strictly speaking one dimensional. However, since the x -coordinate is geometrically related to z , the problem can be treated as such. Therefore the deformation term becomes

$$\frac{\partial(\mathbf{h} \cdot \mathbf{u})}{\partial s_h} = h \left(\sin \varphi \cos \alpha' \frac{\partial u_x}{\partial x} + \sin \varphi \sin \alpha' \frac{\partial u_x}{\partial z} + \cos \varphi \cos \alpha' \frac{\partial u_z}{\partial x} + \cos \varphi \sin \alpha' \frac{\partial u_z}{\partial z} \right), \quad (22)$$

where the derivatives, that are functions of x and z , are made only z -dependent with $x(z) = -z \cot \alpha$. PyTTE computes the strain term from the Jacobian of \mathbf{u} .

3.1 Anisotropic plate

According to [5], the components of the displacement field for an anisotropic plate bent by two (scaled) torques m_x and m_y are

$$u_x = (S_{11}m_x + S_{12}m_y)xz + (S_{51}m_x + S_{52}m_y)\frac{z^2}{2} + (S_{61}m_x + S_{62}m_y)\frac{yz}{2} \quad (23)$$

$$u_y = (S_{21}m_x + S_{22}m_y)yz + (S_{41}m_x + S_{42}m_y)\frac{z^2}{2} + (S_{61}m_x + S_{62}m_y)\frac{xz}{2} \quad (24)$$

$$u_z = -(S_{11}m_x + S_{12}m_y)\frac{x^2}{2} - (S_{21}m_x + S_{22}m_y)\frac{y^2}{2} - (S_{61}m_x + S_{62}m_y)\frac{xy}{2} + (S_{31}m_x + S_{32}m_y)\frac{z^2}{2}, \quad (25)$$

where S_{ij} are the components of the compliance matrix. Thus we find the partial derivatives:

$$\frac{\partial u_x}{\partial x} = (S_{11}m_x + S_{12}m_y)z \quad (26)$$

$$\frac{\partial u_x}{\partial z} = (S_{11}m_x + S_{12}m_y)x + (S_{51}m_x + S_{52}m_y)z + (S_{61}m_x + S_{62}m_y)\frac{y}{2} \quad (27)$$

$$\frac{\partial u_z}{\partial x} = -(S_{11}m_x + S_{12}m_y)x - (S_{61}m_x + S_{62}m_y)\frac{y}{2} \quad (28)$$

$$\frac{\partial u_z}{\partial z} = (S_{31}m_x + S_{32}m_y)z \quad (29)$$

The torques are related to the bending radii R_i by¹

$$\frac{1}{R_x} = -S_{11}m_x - S_{12}m_y, \quad \frac{1}{R_y} = -S_{21}m_x - S_{22}m_y. \quad (30)$$

Thus

$$m_x = \frac{1}{S_{11}S_{22} - S_{12}S_{21}} \left(\frac{S_{12}}{R_y} - \frac{S_{22}}{R_x} \right), \quad m_y = \frac{1}{S_{11}S_{22} - S_{12}S_{21}} \left(\frac{S_{21}}{R_x} - \frac{S_{11}}{R_y} \right). \quad (31)$$

3.2 Isotropic plate

The general anisotropic equations simplify considerably when assuming the plate to be isotropic. The isotropic compliance matrix is given by

$$S = \frac{1}{E} \begin{bmatrix} 1 & -\nu & -\nu & 0 & 0 & 0 \\ -\nu & 1 & -\nu & 0 & 0 & 0 \\ -\nu & -\nu & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 2(1+\nu) & 0 & 0 \\ 0 & 0 & 0 & 0 & 2(1+\nu) & 0 \\ 0 & 0 & 0 & 0 & 0 & 2(1+\nu) \end{bmatrix}, \quad (32)$$

where E is Young's modulus and ν is the Poisson ratio. Plugging these into (31), we obtain

$$m_x = -\frac{E}{1-\nu^2} \left(\frac{1}{R_x} + \frac{\nu}{R_y} \right), \quad m_y = -\frac{E}{1-\nu^2} \left(\frac{1}{R_y} + \frac{\nu}{R_x} \right) \quad (33)$$

and thus

$$\frac{\partial u_x}{\partial x} = -\frac{z}{R_x}, \quad \frac{\partial u_x}{\partial z} = -\frac{x}{R_x}, \quad \frac{\partial u_z}{\partial x} = \frac{x}{R_x}, \quad \frac{\partial u_z}{\partial z} = \frac{\nu}{1-\nu} \left(\frac{1}{R_x} + \frac{1}{R_y} \right) z. \quad (34)$$

Finally, since PyTTE assumes the top surface is at $z = 0$, we need to shift the z -axis $z \rightarrow z + t/2$

¹In this work the signs of R_i is the opposite to that of [5]

4 Crystallography and elastic constants

4.1 Crystallographic vectors

For crystallographic data, PYTTE relies on the internal library of XRAYLIB[6]. The direct primitive vectors \mathbf{a}_1 , \mathbf{a}_2 , and \mathbf{a}_3 given in a Cartesian system are calculated from the lattice parameters a, b, c , α , β , and γ as follows

$$\mathbf{a}_1 = a \begin{bmatrix} 1 \\ 0 \\ 0 \end{bmatrix} \quad \mathbf{a}_2 = b \begin{bmatrix} \cos \gamma \\ \sin \gamma \\ 0 \end{bmatrix} \quad \mathbf{a}_3 = \frac{c}{\sin \gamma} \begin{bmatrix} \cos \beta \sin \gamma \\ \cos \alpha - \cos \beta \cos \gamma \\ \sqrt{\sin^2 \gamma - \cos^2 \alpha - \cos^2 \beta + 2 \cos \alpha \cos \beta \cos \gamma} \end{bmatrix} \quad (35)$$

The reciprocal primitive vectors are calculated according to

$$\mathbf{b}_1 = 2\pi \frac{\mathbf{a}_2 \times \mathbf{a}_3}{|\mathbf{a}_1 \times \mathbf{a}_2 \cdot \mathbf{a}_3|} \quad \mathbf{b}_2 = 2\pi \frac{\mathbf{a}_3 \times \mathbf{a}_1}{|\mathbf{a}_1 \times \mathbf{a}_2 \cdot \mathbf{a}_3|} \quad \mathbf{b}_3 = 2\pi \frac{\mathbf{a}_1 \times \mathbf{a}_2}{|\mathbf{a}_1 \times \mathbf{a}_2 \cdot \mathbf{a}_3|}. \quad (36)$$

The reciprocal vector \mathbf{h} corresponding and normal to the Bragg planes with the Miller indices (h, k, l) is thus

$$\mathbf{h} = h\mathbf{b}_1 + k\mathbf{b}_2 + l\mathbf{b}_3. \quad (37)$$

Crystal directions $[n_1 n_2 n_3]$ are converted to Cartesian vectors (x, y, z) followingly

$$\begin{bmatrix} x \\ y \\ z \end{bmatrix} = [\mathbf{a}_1 \quad \mathbf{a}_2 \quad \mathbf{a}_3] \begin{bmatrix} n_1 \\ n_2 \\ n_3 \end{bmatrix} \quad (38)$$

and *vice versa* by inverting $[\mathbf{a}_1 \quad \mathbf{a}_2 \quad \mathbf{a}_3]$.

4.2 Vector and tensor rotation

A general counterclockwise rotation by θ about axis $\mathbf{u} = (u_1, u_2, u_3)$, with $|\mathbf{u}| = 1$, is given by the matrix

$$Q(\mathbf{u}, \theta) = \begin{bmatrix} \cos \theta + u_1^2(1 - \cos \theta) & u_1 u_2(1 - \cos \theta) - u_3 \sin \theta & u_1 u_3(1 - \cos \theta) + u_2 \sin \theta \\ u_2 u_1(1 - \cos \theta) + u_3 \sin \theta & \cos \theta + u_2^2(1 - \cos \theta) & u_2 u_3(1 - \cos \theta) - u_1 \sin \theta \\ u_3 u_1(1 - \cos \theta) - u_2 \sin \theta & u_3 u_2(1 - \cos \theta) + u_1 \sin \theta & \cos \theta + u_3^2(1 - \cos \theta) \end{bmatrix}, \quad (39)$$

also known as Rodrigues' rotation formula. Rotation is applied to vector \mathbf{v} by the ordinary matrix multiplication $Q\mathbf{v}$. For a 4th order tensor t , the rotated components are

$$t'_{ijkl} = \sum_{p,q,r,s} Q_{ip} Q_{jq} Q_{kr} Q_{ls} t_{pqrs}. \quad (40)$$

In PYTTE, it is taken that $\mathbf{h} \parallel \hat{\mathbf{z}}$, *i.e.* the symmetric Bragg case, corresponds to the asymmetry angle $\phi = 0$. Thus in the most general case the elastic tensors go through the following three rotations:

1. Rotate elastic tensors and direction vectors so that \mathbf{h} is parallel to z -axis
2. Apply a rotation about z -axis to align the crystal directions in xy -plane
3. Apply the asymmetry by performing the rotation of ϕ about y -axis.

Assuming that at least either of h and k is non-zero, the rotation of $\mathbf{h} = (h_1, h_2, h_3)$ (step 1) is performed with the following axis and angle

$$\mathbf{u} = \frac{1}{\sqrt{h_1^2 + h_2^2}} \begin{bmatrix} h_2 \\ -h_1 \\ 0 \end{bmatrix} \quad \theta = \arccos \left(\frac{h_3}{\sqrt{h_1^2 + h_2^2 + h_3^2}} \right). \quad (41)$$

If $h = k = 0$, a rotation of $\theta = \pi$ about $\mathbf{u} = -\hat{\mathbf{y}}$ is applied when $l < 0$; no rotation is needed for $l > 0$. For the in-plane rotation (step 2), the axis is $\mathbf{u} = [0, 0, 1]^T$ and for the asymmetry rotation (step 3) $\mathbf{u} = [0, 1, 0]^T$ and $\theta = \phi$.²

The crystal directions $[n'_1 n'_2 n'_3]$ after a rotation Q are calculated as follows

$$\begin{bmatrix} n'_1 \\ n'_2 \\ n'_3 \end{bmatrix} = (Q \begin{bmatrix} \mathbf{a}_1 & \mathbf{a}_2 & \mathbf{a}_3 \end{bmatrix})^{-1} \mathbf{r} \quad (42)$$

where \mathbf{r} is an arbitrary direction in terms of Cartesian coordinates. (Although not clear from the notation, $Q \begin{bmatrix} \mathbf{a}_1 & \mathbf{a}_2 & \mathbf{a}_3 \end{bmatrix}$ and its inverse are square matrices.)
